INTRODUCTION

Collective oscillatory network dynamics prevail in natural and technological systems alike, including neural and gene regulatory circuits, communication networks, and AC power grids, among others (1–8). A robust function is essential for all of these systems and relies on how their collective dynamics self-organize and respond to external signals. For example, modern power grids are driven dynamically by predictable or random signals, e.g., the fluctuating power feed-in from renewable energy sources, changes in consumer behavior on many time scales, power trading, and failures of infrastructures, all of which cause fluctuations in grid frequency in a nontrivial, distributed way (9). Human brain circuits, as functionally and structurally connected oscillatory networks exposed to external stimuli, exhibit complex activity patterns in a wide frequency band extending up to five orders of magnitude (10, 11). The dynamics of all oscillatory systems essentially underlie system functions, and all are externally driven by planned interference signals, random fluctuations, unit or link failures, etc. Yet, it is not well known how oscillatory network systems respond to such perturbations.

To analyze, understand, and predict the dynamics of coupled oscillators, networks of phase oscillators such as the paradigmatic Kuramoto model are commonly used across fields (12–15). Phase oscillator systems are preferred as generic models because they are simple to simulate, partly analytically accessible, and exhibit a wide range of collective dynamical phenomena observed in oscillatory systems, including synchronization and phase locking, heteroclinic switching dynamics, collective irregular activity, metastable synchronized states, and chimera states (16–21). In neuroscience, Kuramoto oscillator networks capture some basic mechanisms underlying cortical oscillations (15) and frequency-specific correlation patterns in concurrent network from encephalographic recordings (22, 23). Some knowledge about how such networks respond to external driving signals is already established. For instance, regularly and sparsely connected networks of phase oscillators exhibit two response regimes that depend on the frequency content of the driving signals (24, 25). At low driving frequencies, the entire system dynamically responds homogeneously, i.e., all oscillators respond essentially identically. At high frequencies, the dynamical responses are localized on the network (25) and response amplitudes decay with distance, similar to the findings for chains with single, constantly driven pacemaker units (26). For the second-order Kuramoto model, the network response to a local and static perturbation may be localized or delocalized depending on network topology and other parameters (27, 28). However, an overarching theory of how networks respond systematically to dynamical, fluctuating inputs is missing to date such that the range of possible response patterns and the precise mechanisms underlying them are unknown in general, and predicting them remains generally hard if not impossible.

In this article, we develop a theory of dynamic response patterns for oscillatory networks driven by fluctuating inputs. Evaluating a network-wide linear response theory as an explicit function of frequency content of the fluctuating signals, the network’s interaction topology, and the exact location of driving and response nodes, we uncover complex distributed resonance patterns in oscillatory networks with two-dimensional unit dynamics, which are absent in standard phase oscillatory networks with one-dimensional units. These network resonances emerge at intermediate frequency content of the input signals, between global yet homogeneous responses at low frequencies and localized responses at high frequencies (Fig. 1). Resonant responses may be an order of magnitude (greater than 10 times in our examples) larger than static responses that occur in the limit of zero frequencies in the identical network. The theory furthermore explicates the origin and scaling of the localized as well as the homogeneous response patterns present, explaining and generalizing previous works (24–27). The finding and the explanation of the emergence of distributed resonance patterns together with the unifying theory we derive offer explanatory and predictive power across fluctuation-driven systems in nature and engineering.
**RESULTS**

**Model class**

Consider a network of $N$ units $i \in \{1, \ldots, N\}$ with dynamics

\[
\alpha_i \frac{d\theta_i}{dt} + \beta_i \frac{d^2\theta_i}{dt^2} = \Omega_i + \sum_j K_{ij} (\theta_j - \theta_i) + F_i(t) \tag{1}
\]

of phase angles $\theta_i(t)$ and phase velocities $d\theta_i(t)/dt$ at time $t$. Here, $\Omega_i$ is the natural frequency (or acceleration) of unit $i$, and the units interact with coupling strengths $K_{ij} = K_{ji} \geq 0$ via a coupling function $g(\cdot)$. Core parameters $\alpha_i$ and $\beta_i$ in this model class set the relative influences of the rates of change of the phase angles and those of the phase velocities. The phenomena presented below for homogeneous $\alpha_i \equiv \alpha$ and $\beta_i \equiv \beta$ stay qualitatively the same for inhomogeneous systems (see section S1.4). The model class (Eq. 1) generalizes standard phase oscillator networks (13, 14) that are recovered for $\beta = 0$. Taking generically both $\alpha, \beta > 0$ and $g(\cdot) = \sin(\cdot)$ yields coupled second-order Kuramoto models characterizing AC power grids, the swing equation on networks (5, 6, 29), on which we focus in the main part of this article. For such systems, $\theta_i(t)$ describes the mechanical angle of a synchronous machine relative to a reference frame rotating at the nominal grid reference frequency of, e.g., $2\pi \times 50$ Hz in Europe including the United Kingdom [see (5, 6) for details]. Normal stationary operation of a grid is given by a phase-locked state, where Eq. 1 exhibits a fixed vector $(\theta_1, \ldots, \theta_N)$ of relative phases in the absence of any fluctuations [$F_i(t) = 0$]. The functions $F_i(t)$ represent the fluctuations in the production and consumption at unit $i$ and together constitute a high-dimensional, distributed dynamic driving signal to the network. How does the network collectively respond to such dynamic signals?

**Fluctuation-induced dynamic network responses**

Observing the distributed network responses induced by a single local signal, $F_i(t) \sim \delta_{ik}$, already poses puzzles about how the responses depend on the driving and the response unit on the network topology and on the frequency content of the signal, as illustrated in Fig. 1. Specifically, responses to low-frequency inputs appear to be dynamic in time yet homogeneous across the network (Fig. 1, D and E), and responses to high-frequency inputs seem to be localized (Fig. 1, H and I), whereas at intermediate frequencies, responses appear to be irregular in time and across units (Fig. 1, F and G), with severe consequences for the entire collective response pattern (compare Fig. 1, B and C).

To gain analytic insights and thereby intuition about such dynamic response patterns, we start by focusing on the responses generated at one fixed (but arbitrary) unit $k$ by signals of fixed (arbitrary) frequencies $\omega$ and develop a linear response theory expanding in the amplitudes of the response signals into Fourier modes. In a second step, we consider more complex, distributed, and nonperiodic input signals below. Taking $F_i(t) = \varepsilon \delta_{ik} e^{i(\omega t + \phi)}$ and expanding the phase responses to first order in the signal amplitude $\varepsilon$, we obtain

\[
\theta_i^{(k)}(t) = \theta_i^{(k)} + \varepsilon \Theta_i^{(k)}(t) + \varepsilon \eta_i \tag{2}
\]

where

\[
\Theta_i^{(k)}(t) = A_i^{(k)} e^{i(\omega t + \Delta_i^{(k)})} \tag{3}
\]

denotes the oscillatory response at unit $i$ of amplitude $A_i^{(k)}$ and phase $\Delta_i^{(k)}$. $\eta_i = \eta \neq 0$ is an overall homogeneous phase shift that results from the dynamics of the average phase (see section S1.2) and emerges despite zero average input. For each input frequency $\omega$, a matrix equation

\[
[-\omega^2 \beta + i \omega \alpha + L] \Theta^{(k)}(t) = F^{(k)}(t) \tag{4}
\]

thus describes the network response vector $\Theta^{(k)}(t) = (\Theta_1^{(k)}(t), \ldots, \Theta_N^{(k)}(t))$ as a function of time. The network response vector depends

---

**Fig. 1. Fluctuation-induced dynamic response patterns.** A sample network (A) driven by Brownian noise (B) at a single unit $k = 1$ exhibiting (C) complex dynamic response patterns that nonlinearly vary with frequency content of the input signal (D, F, and H) as well as with graph-theoretic distance between the input and the response unit (E, G, and I). Three response classes emerge: homogeneous responses at low frequencies (D and E), spatiotemporally irregular patterns at intermediate frequencies (F and G), and localized responses at high frequencies (H and I). To identify frequency regimes, we selected specific frequency bands [yellow in (D), (F), and (H)] from the spectrum of the original noise realization (B), and all others are displayed in purple. (C), (E), (G), and (I) display the time series of driving signal at unit $k = 1$ (top) and the response in the phase velocities of the units $i \in \{1, \ldots, N\}$ (bottom). In (C), (E), (G), and (I), the time series of the bandfiltered signal are displayed together with the responses (yellow for unit 1 and green for units 2 to 4). Our theory (Eq. S) (thin black lines) well predicts the system responses obtained from direct numerical simulations. (For details of further settings, see Materials and Methods.)
on the perturbation site $k$, the perturbation vector $F^{(k)}$ with only one non-zero component $F^{(k)}_k = \delta_{k\alpha}e^{i(\omega t + \phi)}$, parameters $\beta$ and $\alpha$, and a weighted graph Laplacian matrix $\mathcal{L}$ with elements $\mathcal{L}_{ij} = -K_{ij}\cos(\theta_i - \theta_j)$ for $i \neq j$ and $\mathcal{L}_{ii} = -\sum_{j=1,j\neq i}^{N}\mathcal{L}_{ij}$. As $\mathcal{L}$ is real and symmetric, its $N$ eigenvalues are real, positive in normal operating states where $|\theta_i - \theta_j| \leq \pi/2$ for all edges $(i,j)$. Its eigenvalues are ordered as $\lambda^{[N-1]} > \cdots > \lambda^{[1]} > \lambda^{[0]} = 0$, and its eigenvectors $[\psi^{[0]} \cdots \psi^{[N-1]}]$ form an orthogonal basis. The response vector

$$\Theta^{(k)}_k = e^{i(\omega t + \phi)}\sum_{k=0}^{N-1} \frac{V^{[k]}_k}{-\beta \omega^2 + i\beta \omega + \lambda^{[k]}}\psi^{[k]}_k$$

thus provides a general first-order prediction for the induced response patterns across all connected network topologies [compare (30)].

After a transient time set by the intrinsic dissipation time scale $1/\beta$, this time-dependent vector function (Eq. 5), integrated across the signal’s frequency content, well predicts the dynamic response patterns of the entire network, see, e.g., Fig. 1. We emphasize that the prediction (Eq. 5) immediately generalizes to all network systems described by (Eq. 1) for arbitrary antisymmetric coupling function $g(\theta_i - \theta_j)$. The asymmetry of $g(.)$ ensures a real and symmetric Laplacian matrix and thus the orthogonality of Laplacian eigenvectors.

**Emergence of distributed resonance patterns**

The network response theory presented above provides an analytical expression of steady nodal responses (Eq. 5), thus paving the way to a deeper understanding of the emergent complex response patterns across the network. How does this response theory predict the different response regimes observed (Fig. 1)? More specifically—How can we explicitly extract the dependences of the network response patterns on the frequency of the driving signal, on the network interaction topology, and on the graph-theoretic distance between driving and response units? To reveal more detailed insights, we systematically analyze the response strength of phase velocities $d\theta_i(t)/dt$ to a driving signal at unit $k$ across many orders of magnitude of the frequency and for all response units $i$ in a network. In this section, we assume $\beta = 1$ without loss of generality.

Such responses in phase velocities reflect deviations of the units’ frequencies of power grids from their nominal value $2\pi \times 50$ Hz and are, thus, more directly relevant than deviations in the phase angles themselves. Graphing the response strengths

$$A_i^{(k)}(\omega) = \frac{\omega A_i^{(k)}(\omega)}{\lim_{\omega \to 0} \omega A_i^{(k)}(\omega')} = N_\alpha \omega A_i^{(k)}(\omega)$$

relative to their low-frequency limit clearly indicates the three frequency regimes of characteristic responses (see Fig. 2A).

Dynamic resonance patterns emerge if the signal frequencies $\omega$ are of the same order of magnitude as the eigenfrequencies (see section S2.1)

$$\omega_n^2 = \sqrt{\lambda^{[n]} - \frac{\alpha^2}{4}}$$

for $n \in \{1, \cdots, N-1\}$

The system responds with a distributed, network- and frequency-specific pattern given by Eq. 5 (Fig. 2, A, C, and F). Network resonance patterns are typically heterogeneous, exhibiting no monotonicity in frequency or with respect to the topological distance between the signal and the response unit. In contrast to resonance phenomena in low-dimensional oscillatory systems common in physics and nonlinear dynamics, the response patterns are node specific in a highly nontrivial way. Depending on an overlap factor $[\psi^{[k]}_k]$ of the responding
node $i$ with the driven node $k$ in eigenmode $\xi$, the contribution from the various eigenmodes can be positive, negative, or zero, which leads to different canceling or accumulating total responses for each frequency $\omega$. The overlap factor acts as a node-specific weight in the eigenvector superposition, thus intuitively explaining the complex distributed dynamic response patterns. The response amplitude at resonance peaks may be an order of magnitude larger than for static responses appearing in the limit of $\omega \to 0$ (cf. Fig. 2F).

For frequencies substantially below the eigenfrequencies $\omega_k$, all units exhibit similar response strengths, in particular independent of the topological distance between signal input and response sites (Fig. 2, A and B). At the low-frequency limit $\omega \to 0$, $A_{i}^{(k)}$ approaches $N\alpha$, a constant containing only intrinsic network parameters, not encoding any topology dependence. This explains the observation of homogeneous responses in Fig. 1 (D and E).

For sufficiently large driving frequencies $\omega \gg \omega_k$, the response strengths decay as a power law with frequency. This decay is essentially exponential over the topological distance between signal input and unit response sites (Fig. 2, A and D). Writing the response amplitudes as rational functions of $\omega$, with $\Phi_{ki}^{(d)}$ as coefficients of $\omega^{2d}$ in the numerator of $\Re (\Theta_{\ell}^{(k)} (t))$ (see section S2.1.3), we obtain the first nonzero term with the highest power of $\omega$ in the numerator to be $\Phi_{ki}^{(d)} \omega^{2N-2-2d}$, where $d = d(k, i)$ is the topological distance between the driving unit $k$ and the responding one $i$. The highest power $\omega^{2N}$ appearing in the denominator, thus, yields the exact asymptotic expansion

$$A_{i}^{(k)} (\omega) \sim N\alpha |\Phi_{ki}^{(d)}| \omega^{-2d-1}$$

as $\omega \to \infty$ via definition (Eq. 6). Here, the frequency dependence is encoded solely in the term $\omega^{-2d-1}$. The topological distance $d$ appears explicitly twice, and $\Phi_{ki}^{(d)}$ encodes the overall topological properties of the network as well as the identity of the driving and the responding nodes. This result (Eq. 8) is based on exact zeros of lower-order coefficients (see section S2.1.3 for a detailed derivation) that appear because the relevant matrix element of the $m$-th power of the Laplacian is zero, $(L^m)_{ki} = 0$, if $m < d(k, i)$ as there exists no path from $k$ to $i$ of length smaller than $d(k, i)$. Consequently, for any given frequency in this regime, the response strengths decay approximately exponentially with the distance.

We emphasize that the above analysis about the three regimes of response patterns holds without any assumptions on the network topology, and thus is general for arbitrary interaction structures. See Fig. 3 for an illustration of the generality of the response regimes across different networks.

**Fluctuation-induced distributed resonances**

So far, we have systematically studied the patterns of network responses to trigonometric, sufficiently weak fluctuating signals affecting just one unit in the network. What can we say about the dynamic response patterns in networks with stronger, more irregular, and more distributed driving signals?

For input signals that are both distributed across the network and contain a broad range of frequency components ($\omega > 0$), the linear response theory predicts the units’ responses as a linear superposition across input locations and frequencies via Eq. 5. Specifically, the phase velocity at unit $i$ reads (see section S3)

$$\theta_i^{(\ell)} = \sum_{k \in \Lambda} \left( e^{0,k_{N\alpha}} + \sum_{n} \sum_{k_{N\alpha}} N_{\alpha}^{N-1} \sum_{l=0}^{N-1} - \beta n_{k_{N\alpha}} + i\alpha n_{k_{N\alpha}} + \lambda \right)$$

where $\Lambda$ denotes the set of all units driven by fluctuating signals and $n, k$ labels the dominant Fourier modes with nonzero frequencies at each such unit $k$. The constant drift speed $\frac{\partial \Theta}{\partial t}$ results from the zero-frequency component with magnitude $e^{0,k}$ in the signal at node $k$.

**Fig. 3. Generality of response patterns.** For two exemplary networks, the response patterns for three signals of frequencies representing the three response regimes are indicated by their relative response strengths $A_{i}^{(k)}$ (color coded). Response patterns for (A) to (C), a random tree with $N = 264$, and (D) to (F), the topology of the British high-voltage transmission grid with $N = 120$, both reordered according to graph-theoretic distance from site of driving unit. For both networks, the driven unit is placed at the center with all units displayed on circles with their radii proportional to topological distance (gray concentric rings) in (D) to (F).
Generically, our theory (Eq. 9) has strong predictive power for all combinations of differently fluctuating inputs distributed across the network (see Fig. 4 and more details in Materials and Methods). Moreover, the eigenvector-based overlap factor $v_k^i$ in (Eq. 9) clearly demonstrates how frequency components in the driving signal that are close to the eigenfrequencies induce network-wide resonances in a specific, highly topology-dependent way.

To illustrate how distributed network resonances are induced by a noisy fluctuation signal due to its resonant frequency components, we computed the response time series for a power grid model network with the topology used for Fig. 1A. The fluctuating signals were experimentally recorded from renewable energy sources. The results indicate similarities and notable differences between the responses to the recordings from photovoltaic and wind power sources. Specifically, we find that for both time series samples, fluctuations in wind power and fluctuations in the power from a photovoltaic panel are experimentally recorded from renewable energy sources. The network resonance phenomena across grid nodes. The network resonance phenomena in power grid literature [e.g., (31)]. In strong contrast, our results demonstrate that the frequency responses are indeed highly heterogeneous; therefore, grid frequency makes sense only in the regime of slow-changing driving signals. In particular, anomalous broad-range fluctuations of grid frequencies (9) may, in part, result from the combination of different response patterns to various input fluctuations across grid nodes. The network resonance phenomena here may moreover help to explain how external inputs induce the
complex oscillation patterns in cortical networks, while the bulky slow oscillations and the localized high-frequency oscillations observed in experiments (10) are consistent with our theory.

The phenomenon of resonance was known before from complex dynamic systems if they were driven by external signals that act globally on all units. For instance, in 1981, Benzi reported that stochastic resonance may arise from global, homogeneous periodic forcing of stochastic dynamical systems (32–34). Even earlier (nonstochastic) resonance of molecular excitations was triggered by incident photons with a frequency matching the energy of an electronic transition of the molecule and was exploited in resonance Raman spectroscopy (35). Already in the 1950s, related fundamental phenomena were exploited to reveal energy spectra, e.g., of atomic nuclei (36). The work presented here demonstrates network-wide distributed resonances that emerge in oscillatory networks due to distributed fluctuations impinging distinctly on the different individual units. Previously found “resonances” in networks of (Kuramoto) phase oscillators exhibit a single response peak consistently appearing at zero frequency, independent of the network topology and the system’s natural frequencies (24, 25). In stark contrast, the resonances revealed and explained above are strongly specific to the interaction topology.

Together, our results indicate that external driving on the second dynamical dimension of an oscillator (its variable local frequency) present in the general model class (Eq. 1) induces characteristic dynamic and distributed resonance patterns strongly depending on which units are driven by fluctuations and on how the entire network is connected. The topology and the explicit distance dependence as well as the frequency dependence of the responses revealed here may not only provide a general theoretical prediction of how networks respond to distributed input fluctuations but may also find a range of useful applications. For instance, given the typical frequency content of fluctuation signals at specific units, our theory enables the identification of the most susceptible units in the network and thereby suggests dynamically motivated design constraints and the prevention or mitigation of systemic risks of functional failure.

**MATERIALS AND METHODS**

**Settings for Fig. 1**

Random geometric topology in Fig. 1A was generated according to a stochastic dynamical systems (37), where the cost-versus-redundancy trade-off parameter $r = 0$, meaning line redundancy is disregarded in the network growth. Squares represent generators with rated power inputs $\Omega_i = 30 \text{ s}^{-2}$, and disks represent consumers with power consumption $\Omega_i = 10 \text{ s}^{-2}$. Number of units $N = 80$. For all transmission lines, $K_{ij} = K = 100 \text{ s}^{-2}$, and for all units, $\alpha = 1 \text{ s}^{-1}$. The fluctuation signal was generated by the Wiener process with drift 0 and volatility 1.

**Settings for Fig. 4**

In Fig. 4 (C and D), to assess the quality of the prediction for phase velocity, we define the prediction error as

$$E = \left( \langle \delta \theta_{r.t}^{\text{LRT}}(t) - \delta \theta_{r.t}^{\text{num}}(t) \rangle \right)^2$$

(10)

where $\delta \theta_{r.t}^{\text{LRT}}$ and $\delta \theta_{r.t}^{\text{num}}$ are the phase velocity responses obtained from the above linear response theory (Eq. 9) and direct numerical simulations, respectively. The angular brackets indicate the average over time and over all units in the network. The error bars in Fig. 4C indicate the standard deviation of prediction error across 70 realizations of noisy signals. In Fig. 4D, by proportionally amplifying the power generation and consumption $\Omega_i$ with an incrementally increasing factor $r: \Omega_i \rightarrow r\Omega_i$, we systematically increased the line loads $L_{ij} = |\sin(\theta_i - \theta_j)|$ for every link $(i,j)$ at the steady state and tested the prediction error for the same noise time series as in Fig. 4 (A and B). In the prediction, 50 dominant Fourier components were included. The data points were color coded by the maximum line load in the network under perturbation in a time interval $t = 20 \text{ s}$. The error bars stand for the standard deviation of prediction error over the network. The time average of the prediction error for individual nodes is plotted as light gray lines.

**Settings for Fig. 5**

(A to D) The recordings of the fluctuating power output from renewable energy sources, wind turbines, and photovoltaic panels are obtained from and available under Reference (20) of (38). In the computation of network responses, we used a coarse-grained model of power grids, with each node representing a coherent subgrid. See section S3.2 for details of the model. In Fig. 5E, the nodal response inhomogeneity of node $i$ is defined as the uncorrelated between the response time series of response at node $i$ and the response time series $\langle \delta \theta_i / \delta t \rangle$ averaged across the network: 1 – corr$(\delta \theta_i / \delta t, \langle \delta \theta_i / \delta t \rangle)$, with corr$(x, y)$ being the normalized cross correlation between time series $x$ and $y$.
